2009: Geochemical re-analysis of till samples from the Strange Lake area, Labrador (NTS map sheets 14D/5 and 24A/8). Government of Newfoundland and Labrador, Department of Natural Resources, Geological Survey, Open File LAB/1479, 116 pages.

Cover: Northward-looking view of a 30-m-high esker ridge within an outwash paleo-channel along the southern shore of Strange Lake. This esker contains sediment from the Strange Lake deposit, and in fact, it was in this area that the first mineralized clast associated with the deposit was found. Eskers are prominent features on the Nain Plateau and represent subglacial drainage systems beneath the Laurentide Ice Sheet. The fluted till surface of the Nain Plateau is noted to the west of the esker. Individual flutes are commonly subdued, although large crag-and-tail hills are found. These are important features in understanding dispersal patterns from the Strange Lake deposit.

ABSTRACT

This report provides the results of the re-analysis of till samples collected in the Strange Lake area, northern Labrador in 1983 and 1984. The re-analysis provides geochemical data for 57 elements from 570 BC- or C-horizon till samples, and includes analyses by ICP-ES for aluminum, arsenic, barium, beryllium, cadmium, calcium, cerium, chromium, cobalt, copper, dysprosium, iron, lanthanum, lead, lithium, magnesium, manganese, molybdenum, nickel, niobium, phosphorus, potassium, scandium, sodium, strontium, titanium, vanadium, yttrium, zinc and zirconium; by INAA for antimony, arsenic, barium, bromine, cerium, caesium, chromium, cobalt, europium, gold, iron, hafnium, lanthanum, lutetium, molybdenum, rubidium, scandium, samarium, selenium, sodium, tantalum, terbium, thorium, tungsten, uranium, ytterbium and zirconium. A complete data listing and individual element maps on a bedrock geology base map are also provided.

The source of mineralization is known in this area – the Strange Lake Zr–Nb–Y–Be–REE deposit that was discovered by the Iron Ore Company of Canada in 1979 using boulder-tracing methods, during a follow-up survey to a combined regional fluorine-in-water and uranium-in-lake sediment anomaly. A ribbon-shaped dispersal train, parallel to flow directions from late Wisconsinan, Laurentide ice, extend for at least 40 km. Single-element maps for ore-related geochemical components show that the mineralization is best identified by Be, La, Pb, Nb and Y. The deposit is also defined by Ce, Rb, Th, U and Zr, but not as clearly. Well-defined geochemical anomalies, within the dispersal train, are the result of englacial transport within the ice, and the interception of these debris planes by topographic highs.

INTRODUCTION

This report describes the till geochemistry of the Strange Lake area, northern Labrador, and provides the results of the re-analysis of till samples collected in 1983 and 1984. The initial open file release (Batterson, 1989) provided data on 25 elements, by atomic absorption spectrophotometry, X-ray fluorescence or neutron-activation techniques. This present re-analysis provides geochemical data for 57 elements from 570 BC- or C-horizon till samples, and includes analyses by ICP-ES and INAA, and is the most recent addition to open file releases in Newfoundland (Batterson and Taylor, 2001, 2003, 2004a, 2006, 2007, 2009; Batterson *et al.*, 1998; Liverman *et al.*, 1996, 2000), and Labrador (Batterson and Taylor, 2004b, 2005; Liverman *et al.*, 1993; McCuaig, 2002, 2005). Open file releases of till geochemistry results from these projects have been successful in generating exploration activity, with over 5000 claims staked directly following the release of the data.

This report draws heavily on previous publications on the Quaternary geology and till geochemistry of the Strange Lake area (Batterson, 1989a, b, 1991). It differs from most other till geochemistry open files produced by the Geological Survey of Newfoundland and Labrador, in that the source of mineralization is already known (*cf.*, Batterson and Liverman, 2001). The characteristics and nature of dispersal trains is therefore described in more detail in this report than in others.

The Zr–Nb–Y–Be–REE deposit at Strange Lake (hereafter referred to as the Strange Lake deposit) was discovered by the Iron Ore Company of Canada in 1979 during a follow-up survey to a combined regional fluorine-in-water and uranium-in-lake sediment anomaly. The deposit has estimated reserves of at least 52 million metric tons (Venkateswaran, 1983), and an average ore grade of 3.25% ZrO₂, 0.66% Y₂O₃, 0.12% BeO, 0.56% Nb₂O₅, and 1.3% rare-earth oxides (Dawe, 1984).

LOCATION AND ACCESS

Strange Lake is located approximately 15 km northeast of Lac Brisson, Québec. The Strange Lake deposit is situated approximately 145 km west of Nain, Labrador, on the Labrador–Québec border (Figure 1). The study area consists of NTS map sheets 14D/5 and the Labrador portion of 24A/8, an area of approximately 1010 km², lying between 63°30' and 64°10'W and 56°15' and 56°30'N. The area is accessible using helicopter or fixed-wing aircraft and an overland route to the deposit from the coast is being considered should the deposit be developed. The direction of this route has not as yet been determined and is more fully discussed by Ricketts (1987).

PHYSIOGRAPHY

The study area has been characterized as ‘high plateau’ (Douglas and Drummond, 1955; Lopoukhine

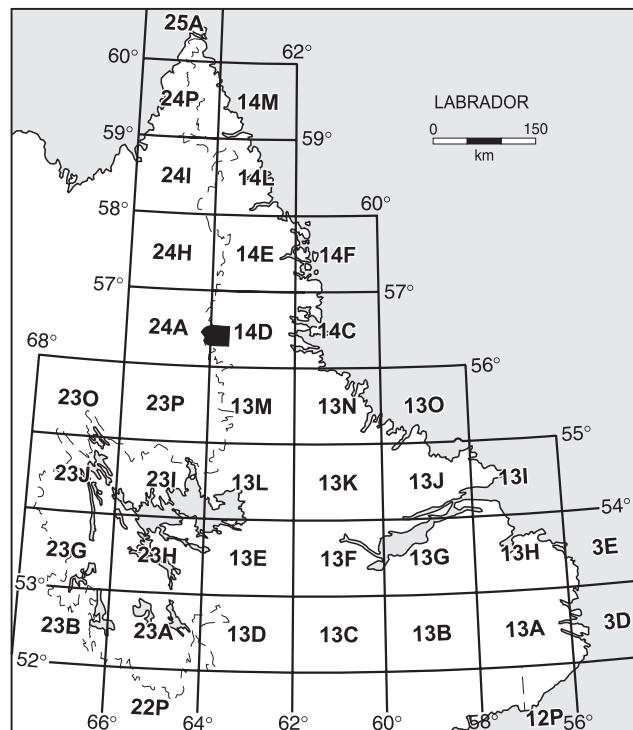

Figure 1. Location of study area.

et al., 1977), although the latter authors refined the description to one of a ‘dissected upland’ comprising a veneer of till over bedrock, commonly drumlinized, along with small areas of bedrock and colluvium. More recently, the terrain features have been described, in detail, by McConnell *et al.* (1984) and Batterson *et al.* (1985). The major topographic feature in the Strange Lake vicinity is a peneplain surface (the Nain Plateau of Ives, 1960a) that was elevated above the sea during the Pliocene (Cooke, 1929). This plateau has a maximum elevation of 700 m above sea level (asl) near the coast, and generally decreases in elevation inland. The Nain plateau is dissected by a number of major river valleys in the vicinity of the study area, *e.g.*, the Fraser, Anaktalik, Ikadlivik, Konrad and Kogaluk River valleys. Of these, the Fraser River valley is the most extensive, penetrating inland for over 100 km, with the lower 60 km forming the fjord, Tasisuak Lake (Plate 1). Valley sidewalls throughout the fjord reach heights of 450 to 500 m. The study area has a mean elevation of 500 m asl, although uplands reach up to 600 m asl. The Strange Lake area lies on the eastern side of the Atlantic Ocean–Ungava Bay watershed, which defines the boundary between Labrador and Québec. Within the vicinity of the deposit, the watershed occurs in an area of subdued relief and is poorly defined.

Plate 1. Panoramic view looking east along the Fraser River valley with Tasisuak Lake in the background. The valley sidewalls are commonly 400-m high. The valley was a major outlet for glacial ice, during the late Wisconsinan.

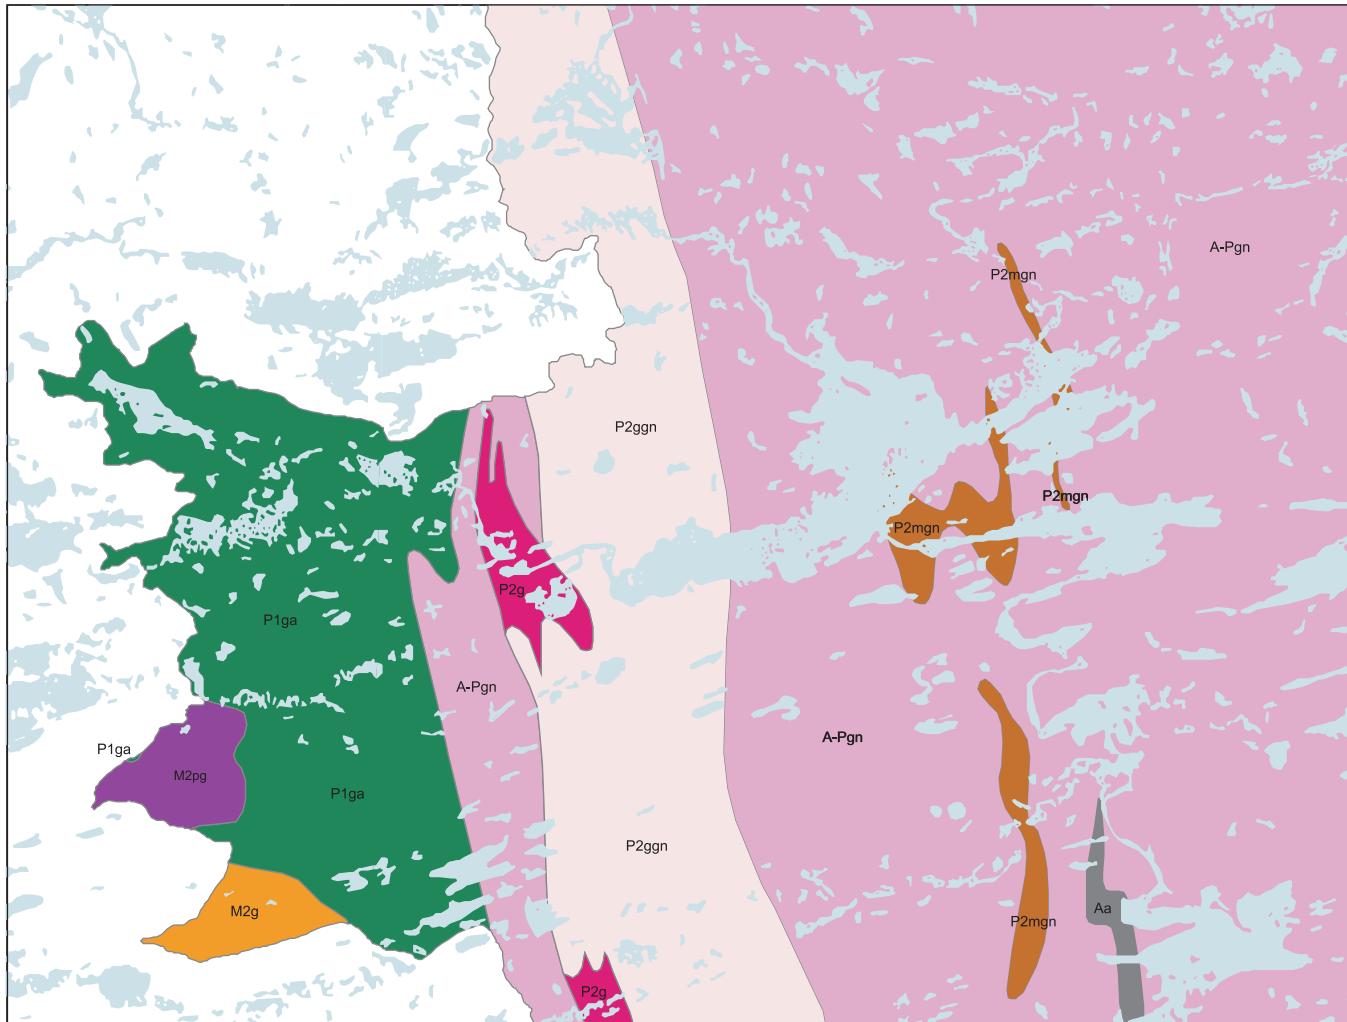

GLACIAL HISTORY

Evidence from numerous sources, both terrestrial and marine, suggests a complex series of glaciations during the Quaternary for most of northeastern North America (e.g., John, 1979; Denton and Hughes, 1981). In the Strange Lake area, however, only evidence of late Wisconsinan glaciation is found and this was the last major phase of glacial activity in northern Labrador. There had been no previous Quaternary research in the Strange Lake area prior to the discovery of the deposit. However, studies have been undertaken on the glaciation and deglaciation of the George River valley to the west (e.g., Barnett and Peterson, 1964), and on the development of weathering zones and deglaciation in the coastal areas around Nain (e.g., Ives, 1978).

The Laurentide ice sheet is considered to have developed through ‘instantaneous glacierization’ of upland surfaces as a result of climatic cooling (Ives, 1957; Ives *et al.*, 1976). Year-round snow on the uplands would alter atmospheric circulation patterns, leading to a lowering of the snowline and a rapid build-up of glacier ice. Ice-flow patterns reveal an essentially radial flow related to an ice dome (or domes) and associated ice divides, located to the east of Hudson Bay (Shilts *et al.*, 1979; Shilts, 1980; Hillaire-Marcel *et al.*, 1980; Dyke and Prest, 1987). Flow was not topographically controlled in the high plateau areas, as confirmed by the oblique orientation of lineated till features across major river valleys, which were probably filled with inactive ice (Ives, 1960b). The Strange Lake area was completely covered by ice during the late Wisconsinan. The lack of recessional moraines and the widespread presence of glaciofluvial features suggest deglaciation probably occurred by downwasting rather than a recessional process, exposing the coastal highlands first (Ives, 1960b). Deglaciation commenced about 10 500 years BP on the Labrador coast (Short, 1978) and progressed in a southwesterly direction. As the Laurentide ice sheet receded over the Atlantic Ocean–Ungava Bay watershed, a succession of proglacial lakes developed, ponded between inland ice situated over Ungava Bay to the north, and the Labrador–Ungava plateau to the west and south, and the highlands to the east (Ives, 1960a). The proglacial lake system is named Lake Naskaupi-McLean (Ives, 1960a), although the two lakes were only united during the initial stages of development. Radiocarbon dates from basal lake sediments record initial lake development postdating 8700 years BP and provide an approximate date for deglaciation of the Strange Lake area. The analysis of the shorelines (to Naskaupi 2, the largest of three known lakes) reveals that they are tilted to the southwest (Barnett and Peterson, 1964), which provides additional evidence that the Labrador–Ungava peninsula was a major ice-dispersal centre. Eventual drainage of glacial Lake Naskaupi-McLean occurred as successively lower outflow channels were exposed, primarily through the Kogaluk River system (Barnett and Peterson, 1964), with lesser discharge routes via the Fraser River and other more southerly outlets (Prest *et al.*, 1968). The Strange Lake area was unaffected by major drainage from Lake Naskaupi-McLean, although the elevation and position of the area relative to the proglacial lakes suggests some outflow was likely.

BEDROCK GEOLOGY OF THE STRANGE LAKE AREA

Apart from studies of the peralkaline granite complex, which hosts the Strange Lake deposit, the field area has been mapped by Taylor (1970, 1979), and Ryan *et al.* (1988, 2003; Figure 2). The geology consists of Mesoarchean and Paleoproterozoic gneiss and associated rocks. These rocks are generally medium-grained, variably migmatized mafic gneiss (amphibolite, mafic granulite, gabbronorite) (Ryan *et al.*, 2003), although variations in texture and colour are common. Younger late Paleoproterozoic medium- to

Middle Mesoproterozoic

Strange Lake Intrusive Suite

M2pg Fine- to medium-grained, rare-metal-enriched, peralkaline, arfvedsonite granite.

Early Mesoproterozoic

Napeu Kainiut Intrusion

M2g Hypidiomorphic quartz monzonite and granite

Late Paleoproterozoic

P2g Massive to weakly foliated, generally medium- to fine-grained, pink biotite +/- muscovite granite

Early Paleoproterozoic

P1ga Metamorphosed suite of plutonic rocks. Mostly fine-to medium-grained gabbronorite and foliated to gneissose derivatives

P2gn Dark-grey-weathering, biotite and hornblende-rich gneiss and intercalated mafic gneiss, intruded by several generations of medium-grained to pegmatoidal granite

Archean and Paleoproterozoic

P2mgn Dark-grey, dark-green and black weathering, generally medium-grained, variably migmatized, amphibolite, mafic granulite and gabbronorite

Neoarchean and Paleoproterozoic

A-Pgn Undivided and diverse group of buff-, white-, grey- and pink-weathering gneissic rocks

Paleoarchean and Mesoarchean

Aa Predominantly white-weathering, locally quartz-bearing, recrystallised and foliated anorthosite and leucogabbronorite and migmatised variants

Figure 2. Bedrock geology of the Strange Lake area (modified from Ryan et al., 2003).

fine-grained, biotite ± muscovite granite and early Mesoproterozoic hypidiomorphic quartz monzonite (Napeu Kainiut Intrusion; Ryan *et al.*, 2003) are intruded in the western and central part of the study area. The reader is referred to Ryan *et al.* (2003) for more detailed descriptions of the bedrock geology of the area.

Detailed bedrock mapping by Zajac *et al.* (1984) and Miller (1986, 1990) defined the Strange Lake Intrusive Suite as hosting the Strange Lake deposit. This deposit is hosted within a 1271 ± 30 Ma (Zajac *et al.*, 1984) peralkaline granite intrusion having an irregular ovoid (8 by 6 km) surface expression, occupying a surface area of about 32 km². The margins of the Strange Lake peralkaline granite are delineated by a ring fault, which is a prominent fluorite and fluorite–hematite bearing breccia zone, dipping toward the northwest at about 20 to 35° (Zajac *et al.*, 1984). Mineralogically, the Strange Lake peralkaline granite is made up of quartz, feldspar (albite + K-feldspar, or microperthite), riebeckite and aegerine. The Strange Lake deposit is ‘strange’ because it contains some rare and, until recently, unnamed minerals and is enriched in many incompatible elements (Miller, 1986). These ‘exotic’ minerals and their associated ore elements include elpidite (Na-Zr silicate), and gittinsite (Ca-Zr silicate), plus pyrochlore (Nb, Ta), armstrongite (Zr), gadolinite (Y, Be), kainosite (Y), fluorite, allanite (Ce, Y), sphene, zircon, thorite and narsarsukite [(Na-Ti), Fe silicate] (Zajac *et al.*, 1984; Currie, 1985; Miller, 1986). On the basis of the relative proportions of these ‘exotic’ minerals, Miller (1986, 1990) has subdivided the complex into three discrete units. The exotic-poor phase contains less than 5 percent ‘exotic’ minerals and comprises about 70 percent of the complex, predominantly the outer margins; the exotic phase contains 5 to 10 percent and locally up to 15 percent ‘exotic’ minerals and occupies the central part of the complex; and the exotic-rich phase contains greater than 10 percent exotic minerals and has the highest grade mineralization. The exotic-rich phase is the smallest unit in area (approximately 1 km²) but contains up to 2.4 percent ZrO₂, 3.3 percent Y₂O₃, 0.9 percent Nb₂O₅, 1.5 percent BeO and 2.6 percent total REEs. These major groups can also be subdivided on the basis of grain size, and the presence or absence of inclusions.

THE QUATERNARY GEOLOGY OF THE STRANGE LAKE AREA

GLACIAL EROSIONAL FEATURES

Although the area is heavily drift covered, two major types of erosional features are present; rôches moutonées, and striations. Rôches moutonées are oriented parallel to glacial flow, and have a pronounced asymmetric profile (Plate 2). They are commonly less than 3 m high and are formed through abrasion on the up-glacier side, and plucking by freeze-thaw within a cavity on the down-glacier side (Sugden and John, 1976). Rôches moutonées occur over the entire study area and provide a clear indication of the subglacial environment. In the Strange Lake area, rôches moutonées are oriented between 060 and 070°, trending more northward in the east compared to the west. Variations of striae directions around rôches moutonées indicate that ice was moulded around the outcrops and this reflects plastic flow conditions at the base of the ice. (Striations are linear abrasions that are made on exposed bedrock/clast surfaces by debris transported at the base of the ice. They are good indicators of glacial-flow direction because they form parallel to the ice flow.) The effectiveness of abrasion is dependent on the presence and the continued supply of debris to the glacier bed plus actively sliding basal ice. Ice thickness, particle and bedrock characteristics, and the presence of basal water, are also important factors in affecting the rate and type of abrasion (Sugden and John, 1976). In the Strange Lake area, striations have three distinct forms

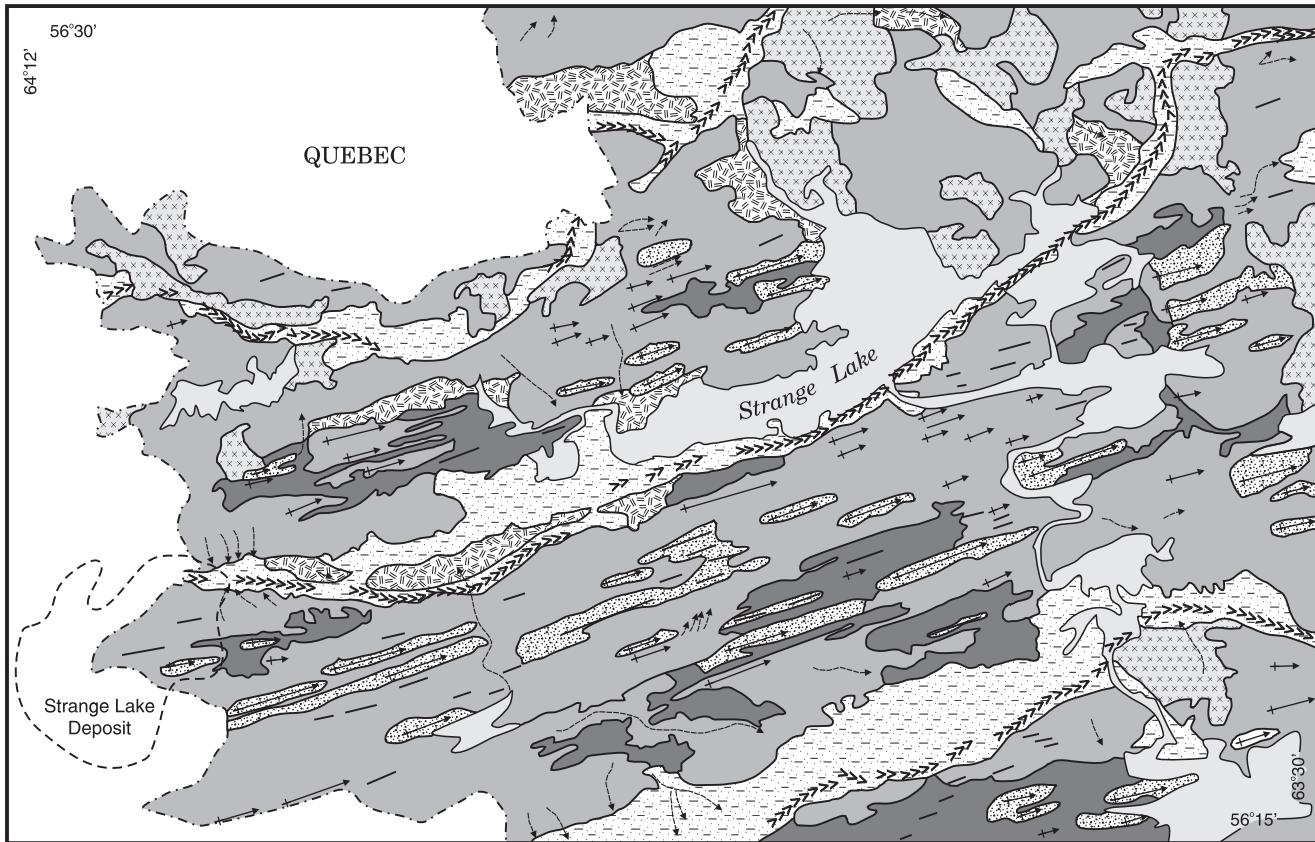

Plate 2. *Rôche moutonnées* at Strange Lake. Ice flow in direction of arrow.

(scratches, nail-heads and grooves) that occur at micro- and macro-scales. Micro features (2 cm in length, by 0.2 cm in depth and width) are non-directional striations and directional ‘nail-head striations’, with their heads located in the down-ice direction; they are relatively rare, except on fine-grained xenoliths, because the medium- to coarse-grained bedrock is not conducive to the preservation of this type of striation. More common are macro-scale grooves (20- to 100-cm long by 5- to 20-cm wide and 0.5- to 3-cm deep). The trend of the grooves is consistent with striae, commonly cutting across the structural grain of bedrock on which they are found. In places, micro-scale striations occur within the macro-scale grooves. Only one ice-flow direction has been found in the study area. Deflection of ice around bedrock outcrops is shown by diverging and converging striations on the up-ice and down-ice sides of outcrops respectively.

GLACIAL DEPOSITS

The glacial depositional environment is characterized by constructional landforms (*e.g.*, flutes, crag-and-tail hills, eskers) and consists of glacigenic diamicton and gravel (Figure 3).

LEGEND

Post-glacial

- Organics : Poorly drained bog of variable thickness. Commonly overlies till

Glacial

- Glaciofluvial veneer : Thin (<1m) cover of fine- to medium-sand and associated gravels over till or bedrock
- Glaciofluvial : Generally fine- to medium-stratified sands and associated gravels. Generally, confined to paleochannels. Gravel-rich esker ridges (5-25 m) are common
- Streamlined Till : Till with fine sand matrix. 10-30% clast content, some fine sand to silt lenses. Probably of basal origin. Occurs as flutes or crag-and-tail hills up to 50m high and 5000m long
- Till : Description as above. Surface may have gullied or featureless expression. Commonly greater than 2m thick

Pre-glacial

- Bedrock : Area dominated by bedrock. Numerous pockets (<1m thick) of glaciogenic sediment common

SYMBOLS

- Ridge parallel to flow
- Crag-and-tail hill
- Esker
- Meltwater channels

Figure 3. Surficial geology of the Strange Lake area (modified from Batterson, 1989b).

Diamicton

Three types of diamicton were identified in the study area.

Type I. This type is a thin (50 to 60 cm), massive, over-consolidated diamicton having a silty to fine sandy matrix, and striated clasts of predominantly local origin. Anomalous Strange Lake deposit-related element values and radiometric levels that are considerably higher than the overlying sediment correspond to the mineralized bedrock that it directly overlies, and is suggestive of a local origin for this material. Together, these characteristics suggest a subglacial (lodgement?) genesis *i.e.*, deposited from the sliding base of a dynamically active glacier by pressure melting and/or other mechanical processes (Ashley *et al.*, 1985). This type was identified in the trench excavated by the Iron Ore Company of Canada to expose exotic-rich bedrock.

Type II. This type is a normally consolidated diamicton that has a sandy to silty matrix. It contains thin (less than 2 to 3 cm), well-sorted lenses of fine- or medium- sand. Irregularly shaped inclusions (2 to 3 mm diameter) of pink sand (possibly related to the peralkaline granites) are also found. This type lies stratigraphically above diamicton Type I in one locality and is common throughout the field area. Distinct geochemical and radioactive breaks occur between this type and the underlying one (Batterson, 1989). Strange Lake deposit-related element values and the radioactive response are lower than the underlying diamicton type (Type I), and suggest that this unit contains a higher proportion of far-travelled clasts and matrix than the underlying Type I diamicton. Within the Iron Ore Company of Canada trench, up to 3 m of Type II diamicton are exposed. The characteristics of this sediment are consistent with those of a subglacial melt-out till *i.e.*, a till formed by the slow release of debris from glacier ice that is not sliding or deforming internally (Ashley *et al.*, 1985).

Type III. This type consists of boulders and clasts that are angular to sub-angular and are not striated. In all cases they directly overlie diamicton Type II. These boulder concentrations occur in close association with areas of glaciofluvial sediment in the southern, central and northern parts of the field area. The boulders in the south-central area are distal in origin, whereas those in the north are all of local origin. This is the uppermost stratigraphic unit and may be supraglacial in origin.

Glaciofluvial Sediments

Glaciofluvial outwash is restricted to a series of paleochannels in the southern, central and northern parts of the study area. In these channels, there is a veneer of dominantly sand-sized material overlying bedrock or diamicton and distinct gravelly esker ridges. The outwash channels are wide (commonly wider than 2 km) and contain numerous areas of bedrock, kettleholes, and hummocks comprising melt-out till covered by a veneer of boulders. Hummocks may represent the discharge of (frozen?) blocks of diamicton from the downwasting ice sheet and their subsequent melting out within the outwash system.

Organic Sediments

Organic sedimentation in the Holocene is common across the area. These sediments reflect poorly drained terrain and commonly form a veneer over till. The organic veneer is found at all elevations and is not restricted to low lying areas.

Lacustrine Sediments

Minor areas of fine-grained sediments related to postglacial wave reworking of primarily outwash sediments were observed around Strange Lake and other lakes in the area, although generally not as contiguous units that could be mapped.

OVERBURDEN THICKNESS

Overburden thickness data were calculated from drill logs, contained within Iron Ore Company of Canada assessment reports, covering a claim area of about 35.6 km² on NTS map sheet 24A/8. The maximum recorded overburden thickness within this area is 18.6 m, the average being between 4 and 6 m (Batterson, 1989a). Quantitative data is not available on overburden thickness outside the Iron Ore Company of Canada's claim areas. Thin overburden was noted within some of the outwash channels and in the proximity of bedrock crags. Areas of thicker drift are expected in till tails, which reach heights of 30 m down-ice of bedrock crags. Overburden cover, which decreases in thickness in the northeastern quadrant of the study area, mainly consists of a concentration of locally derived diamicton overlying bedrock. The reason for the thinner drift in the area is unclear but may relate to its topographic setting up-ice of an upland. The consequent compressive flow regime may have resulted in continued erosion, and deposition only occurring during deglaciation.

GEOMORPHOLOGY

The Strange Lake area is dominated by several glacigenic features.

Crag-and-tail hills: These are streamlined landforms that have a complex depositional history. They are elongate hills, having a steep, narrow, up-ice side and a gentle, long, down-ice profile (Plate 3). The crest is commonly associated with a bedrock knob; the crag. Crag-and-tail hills are common features in the Strange Lake area; the dimensions vary considerably, ranging from small-scale features 5-m high and 100-m long, to large 50-m high and 4-km long hills. No sections exist through the crag-and-tail hills and therefore the internal structure is unknown. Shallow test-pits reveal sediment with characteristics consistent with diamicton Type II, *i.e.*, sediment deposited by subglacial melt-out. The crags, especially the higher ones, are commonly composed of amphibolite facies or quartzofeldspathic gneiss. Hillefors (1973), Sugden and John (1976), Boulton (1982) and others suggest that the genesis of crag-and-tail hills may be associated with that of glacial flutes and correspond to the development of cavities down-ice of a boulder or bedrock obstruction. A cavity develops where ice flows over a high point on an irregular bedrock surface. The shape and dimensions of the cavity, and thus the tail, are determined by a series of factors, including horizontal and vertical ice-velocity, height of the bedrock hump and its length parallel to flow, and subglacial hydrostatic pressure (Boulton, 1982; Eyles, 1983). Crag-and-tail hills occur where water-saturated diamicton is squeezed into a cavity that has a low confining pressure compared to surrounding areas (Sugden and John, 1976). It is likely that the formation of crag-and-tail hills in the Strange Lake area is a result of a combination of processes, including migration of material into a cavity or low pressure zone, erosion and subsequent deposition of material derived from the crags, either by subglacial melt-out from the glacier sole, or lodgement of sediment where the sole comes into contact with the substratum. This diamicton, deposited in the lee of an obstruction, has been termed 'lee-side till' (Hillefors, 1973). Sand and silt lenses observed within the diamicton, and near the surface (upper 1 m), imply that the glacier sole was not always in direct contact with the tail-forming material because these structures

Plate 3. Crag-and-tail hill in the Strange Lake area. These features commonly showed anomalously high geochemical values compared to surrounding areas, somewhat independent of distance from source. This led Batterson (1989b) to speculate that these topographic highs 'intercepted' complex-derived sediment transported either englacially or high in the basal debris layer.

would unlikely survive active ice modification. On the up-ice side of bedrock crags, till 'ramps' are common. They are more steeply sloped than till tails, and are formed as debris-rich basal ice either stagnates or is lodged on the proximal side of an obstruction; ice on the up-glacier side consequently shears over and around the new obstruction (Eyles, 1983). The debris-rich ice melts-out *in situ* although lodgement on the upper surface is likely as till-ice contact is maintained (Boulton, 1970, 1982). Therefore, it may be expected that this stoss-side material is more compacted than that in the lee of the crag (Hillefors, 1973).

In the Strange Lake area, the crag-and-tail hills have a distinct asymmetric profile, the south-facing side being steeper than the north. This asymmetry is likely the result of postglacial snow patch accumulation on the south-facing slopes and the accelerated erosion of these slopes during the melt season.

Eskers: The dominant features within the outwash terrain are esker ridges. These are well-defined forms 10- to 30-m high and 50- to 200-m wide (Cover photo). Individual ridges are commonly dissected

by meltwater channels, or by lakes, although the esker systems are continuous for more than 50 km (Ricketts and Hayes, 1985), terminating in major post-glacial drainage systems. Most major eskers occur along the southern margin of outwash channels, presumably reflecting the regional slope.

PERIGLACIAL FEATURES

Periglacial features are the result of postglacial modification of glacigenic deposits by freeze-thaw action. Three major types of periglacial features are observed, although not as mapped units. All features are active and reflect the fact that the Strange Lake area lies within the zone of discontinuous permafrost.

Mudboils: Mudboils are diapiric structures caused by the injection of fine-grained material into near-surface horizons through a process of hydrostatic pressure build-up during the freezing season (French, 1976; Shilts, 1978) and subsequent upward release of pressure. They are common features in the Strange Lake area, on partly- to well-drained till surfaces. On the surface, mudboils are circular in shape where the angle of slope is less than 2°, devoid of vegetation and commonly have a capping of clasts resulting from a process of upfreezing and the winnowing of fines. They range from centimetres to several metres in diameter, and may occur singularly or in groups separated by organic mounds. Mudboils destroy the structure of existing soils but relict soil is commonly observed along the margins of mudboils as it is being reincorporated into the subsurface. On slopes greater than 2°, mudboils take on an elongate form.

Polygons: Well-developed hexagonal-shaped polygons were observed in till at several isolated localities in the Strange Lake area. The origin of this patterned ground phenomena is not clear, although it is likely that cracking is the result of, thermal contraction, seasonal frost, or dessication, the latter process being independent of the need for permafrost. Washburn (1973) suggested that dessication through wind action is the most likely cause of the small, non-sorted polygons that characterize many upland tundra sites.

Solifluction Terraces: The downslope movement of sediment through a combination of gelifluction and frost creep is a common feature of a periglacial landscape. Solifluction terraces form a stepped, tread-like slope that ranges from 3 to 5°, up to 15 to 20°. The relief of these features is less than 1 m in the Strange Lake area. The level part of the terrace is commonly devoid of vegetation, suggesting solifluction is still active.

REGIONAL SURFICIAL SEDIMENT SAMPLING

SAMPLING AND SAMPLE PREPARATION METHODS

Sampling was carried out during the summers of 1983 and 1984. Quaternary deposits, predominantly till, were sampled from over 550 sites and 1081 samples were collected (Batterson, 1989a). Most samples were from the C- or BC-soil horizon, taken at about 0.5 m depth in test pits. This provided a nominal sample density of 1 site per 1.97 km, although in the vicinity of the Strange Lake complex, the sample density increased to about 1 site per 0.5 km² or less. Soil profile sampling of B-, BC- and C- horizons has been completed, and these data are reported in Batterson (1989a, 1989b). This report provides re-analysis of the BC- or C-horizon samples from each site, and contains data on 539 samples (Figure 4).

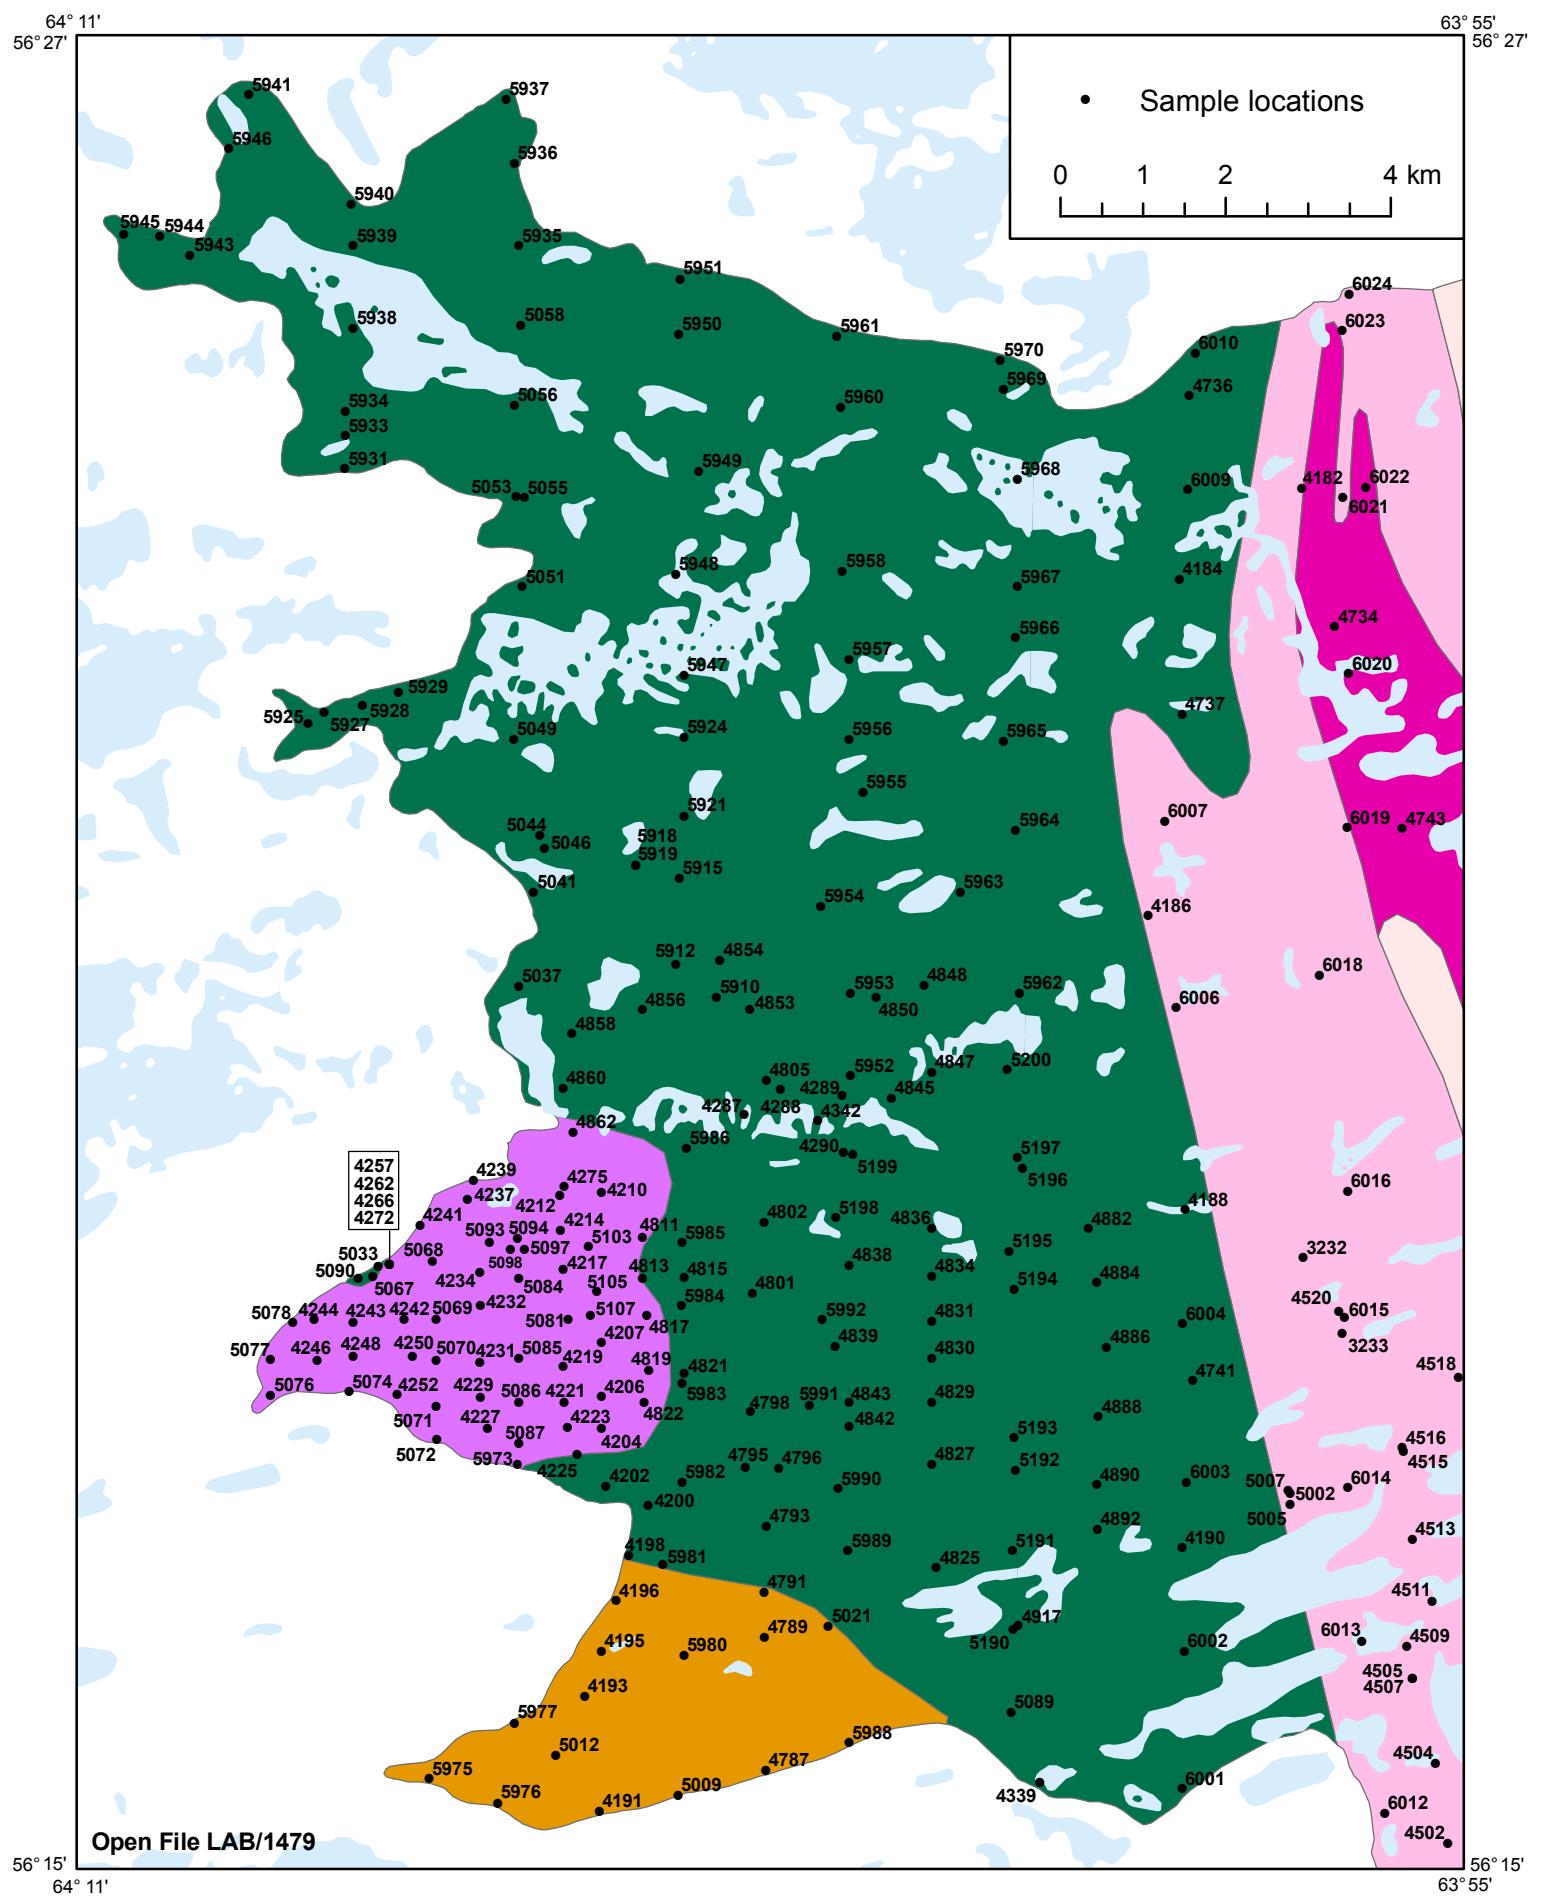

Figure 4a. *Map showing locations of till samples.*

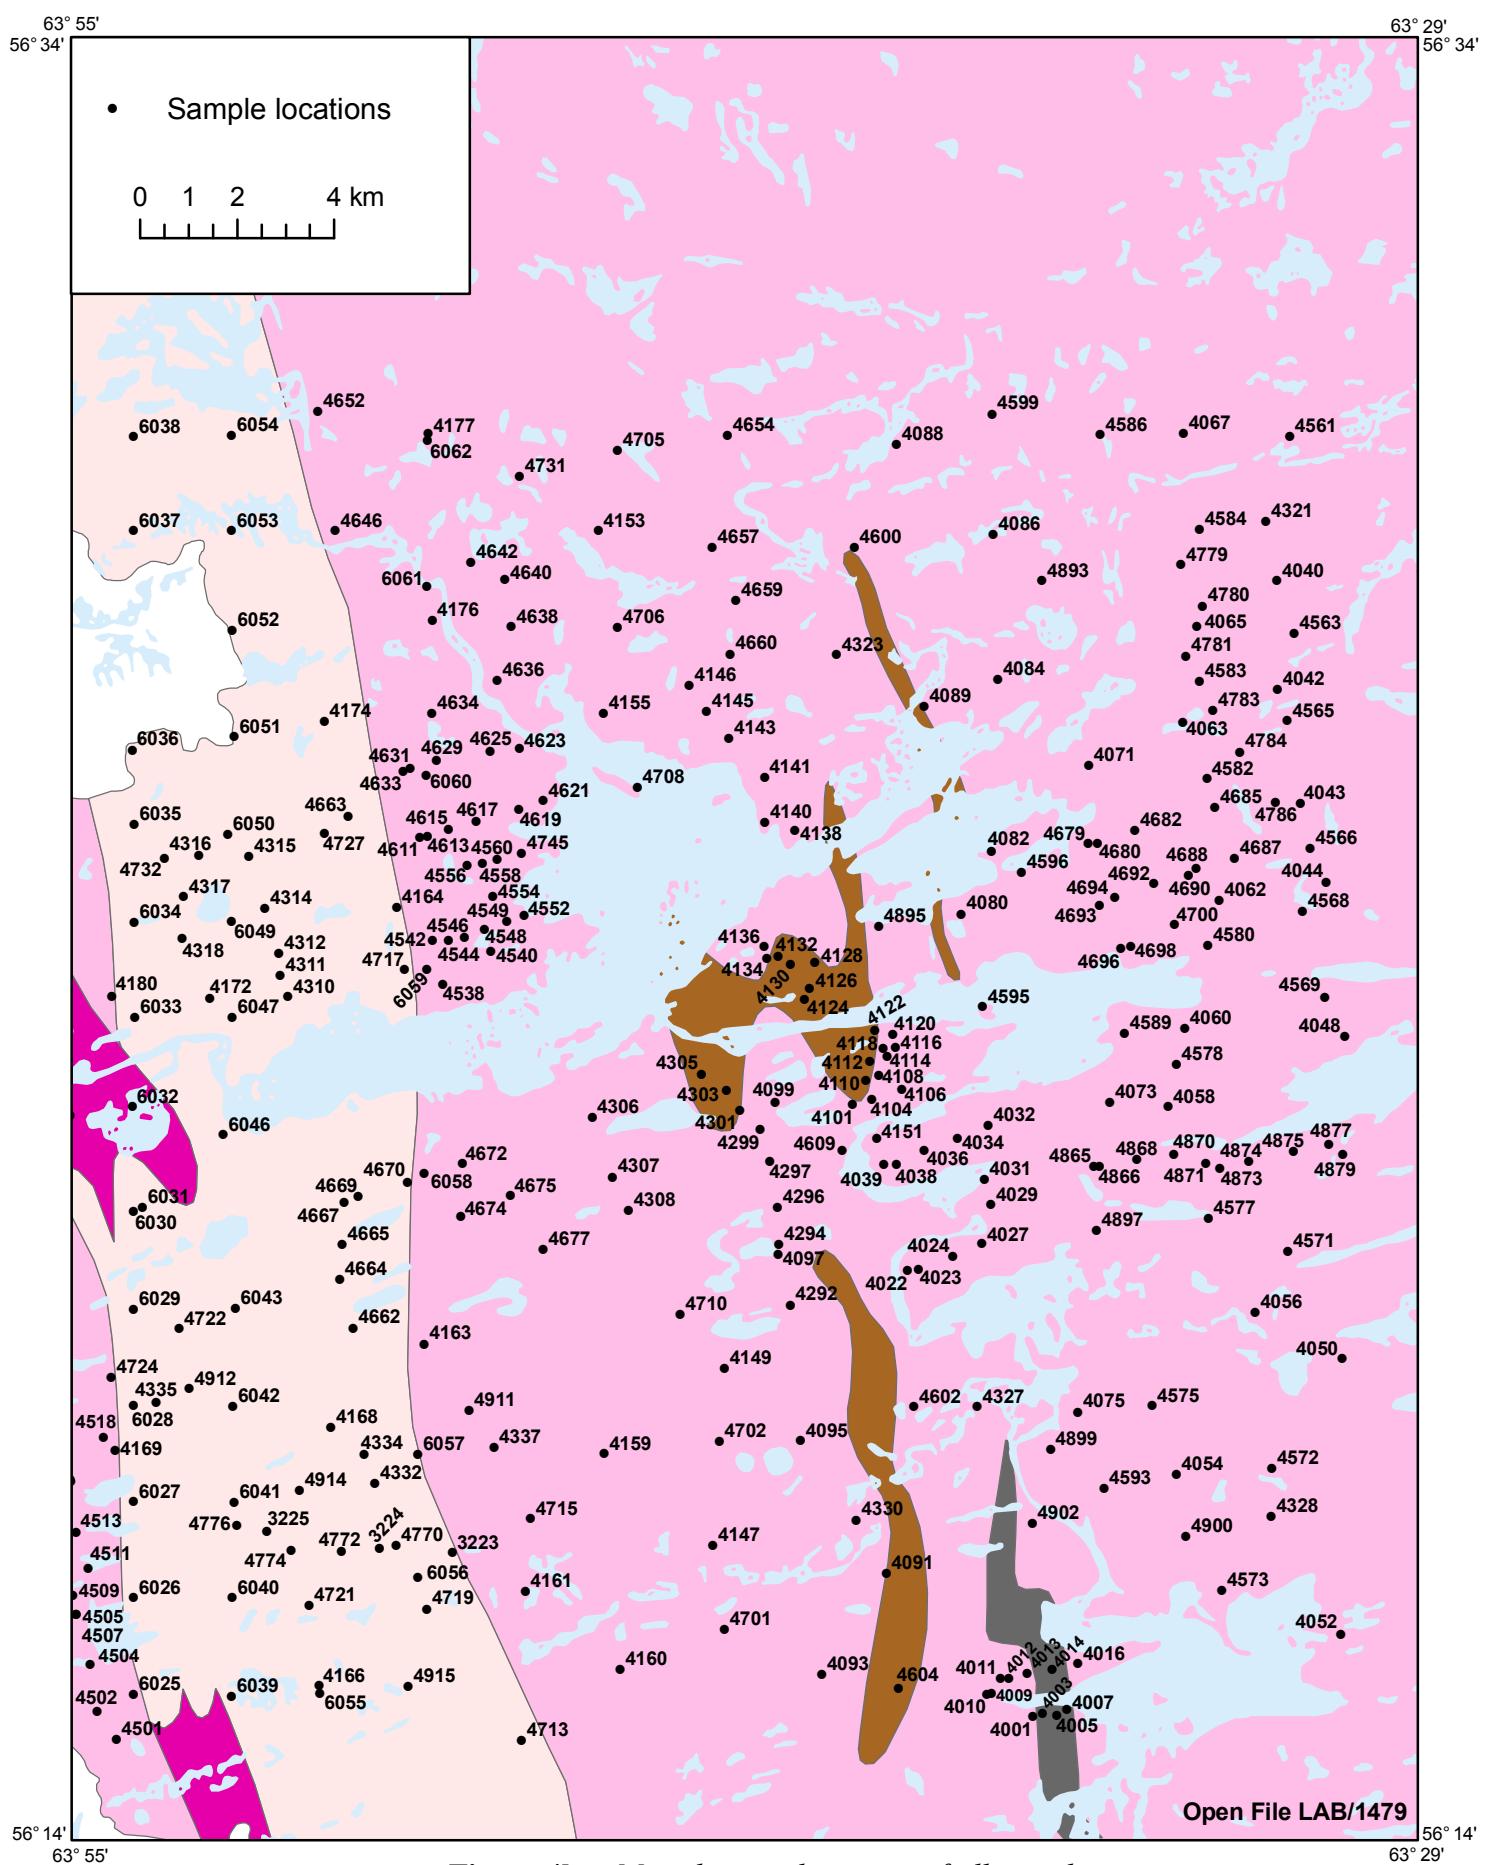

Figure 4b. *Map showing locations of till samples.*

In the field, samples were placed in kraft-paper sample bags, and sent to the Geological Survey's Geochemical Laboratory in St. John's, where they were air-dried in ovens at 40°C and dry-sieved through 180 µm stainless steel sieves.

GEOCHEMICAL ANALYSIS

Analytical work was carried out at the Geological Survey's Geochemical Laboratory, and additional analyses were analyzed using a commercial laboratory. The appended data listings (Appendix A) contain all the field and analytical data from the sediment survey. To distinguish the different analytical methods/laboratories, the trace element variables are labelled with a combination of the element name, a numeric code and the unit of measurement.

A complete list of variables is given in Table 1, and a full listing of field and geochemical data is contained in Appendix A.

ANALYTICAL METHODS

Inductively Coupled Plasma–Emission Spectrometry (ICP-ES)

For these analyses, the procedures outlined by Finch (1998) are followed. One gram of sample is weighed into a 125 ml Teflon beaker, and 5 ml of concentrated hydrochloric acid, 15 ml of concentrated hydrofluoric acid, and 5 ml of 1:1 perchloric acid is added to each sample. The samples are placed on a hotplate at 200°C and evaporated to dryness, after which the beakers are half-filled with 10% hydrochloric acid and returned to the hotplate at 100°C. When the residue is completely dissolved the samples are removed, cooled and transferred to 50 ml volumetric flasks. One ml of 50 g/l boric acid is added to each sample to complex any residual hydrolflouric acid. The samples are made to volume and analyzed by ICP-ES (Licthe *et al.*, 1987). For most elements dissolution is total; exceptions are Cr from chromite, Ba from barite and Zr from zircon. Accuracy can be judged from the results for reference materials (Table 2).

Values for the following elements were determined: Aluminum, barium, beryllium, calcium, cerium, cobalt, chromium, copper, dysprosium, iron, gallium, potassium, lanthanum, lithium, magnesium, manganese, molybdenum, sodium, niobium, nickel, phosphorus, lead, scandium, strontium, titanium, vanadium, yttrium, zinc and zirconium (Al₂, Ba₂, Be₂, Ca₂, Ce₂, Co₂, Cr₂, Cu₂, Dy₂, Fe₂, Ga₂, K₂, La₂, Li₂, Mg₂, Mn₂, Mo₂, Na₂, Nb₂, Ni₂, P₂, Pb₂, Rb₂, Sc₂, Sr₂, Ti₂, V₂, Y₂, Zn₂ and Zr₂, respectively).

Instrumental Neutron Activation Analysis (INAA)

This analysis was carried out at Becquerel Laboratories, Mississauga, Ontario. On average 24 g of sample was used for the analysis and the samples (with duplicates and control reference materials included incognito) were weighed and encapsulated in the Geochemical Laboratory of the Department of Natural Resources in St. John's. Samples were irradiated with flux wires and an internal standard (1 for 11 samples) at a thermal neutron flux of 7×10^{11} n/cm²s. After 7 days (to allow Na²⁴ to decay), samples are counted on a high purity Ge detector that has a resolution of better than 1.7 KeV. Using the flux wires, the decay-corrected activities are compared to a calibration developed from multiple certified international reference materials. The standard present is only a check on accuracy of the analysis and is not used

Table 1. Variable list and description of data

VARIABLE	DESCRIPTION	VARIABLE	DESCRIPTION
Sample	Unique sample ID. First two numbers represent year (e.g., 83 = 1983)	La2 ppm	Lanthanum, ppm, by ICP

for calibration purposes. Between 10 and 30 percent of the samples are checked by re-measurement. Accuracy can be judged from the results for reference materials (Table 3).

Total contents of the following elements were determined quantitatively: arsenic, gold, barium, bromine, cerium, cobalt, chromium, cesium, europium, iron, hafnium, lanthanum, lutetium, molybdenum, sodium, rubidium, antimony, scandium, selenium, samarium, strontium, tantalum, terbium, thorium, uranium, tungsten, ytterbium and zirconium. (As1, Au1, Ba1, Br1, Ce1, Co1, Cr1, Cs1, Eu1, Fe1, Hf1, La1, Lu1, Mo1, Na1, Rb1, Sb1, Sc1, Se1, Sm1, Ta1, Tb1, Th1, U1, W1, Yb1 and Zr1 respectively).

QUALITY CONTROL

Data quality was monitored using laboratory duplicates (analytical precision only). These data are verified at the laboratory and are not included in this report, but are available upon request (by writing to the first author). Accuracy estimates are provided by the results from standard reference materials analysed with them (Tables 2 and 3). These data show that for almost all elements, Zr2 being an exception, all data is of high quality.

Data from duplicate samples taken from the same site are presented in Table 4. The extent of correlation (Pearson) of these data provided a measure of data reproducibility that can be used to estimate data quality. Identical results of duplicate samples show a correlation coefficient of 1.000. For some elements, the analysis of duplicates yields poor correlations, commonly because samples contain levels that are close to the detection limit for that element. Most samples yielded results below detection limit for Au1, Br1, Cs1, Mo1, Ni1, Se1, Ta1, Tb1, U1, W1 and Zr1, and for this reason it is difficult to evaluate data quality for these elements.

It should be emphasized that for mineral exploration, the relative variation of an element is of primary concern. Of the 44 elements determined, 12 were determined by both ICP-ES and INAA (As, Ba, Ce, Co, Cr, Fe, La, Mo, Na, Rb, Sc, Zr). To reduce the size of the data for presentation and statistical analysis, for these 12, the data from the method with the best quality determined from comparison with laboratory and field duplicates have been used (*i.e.*, As1, Ba2, Ce2, Co2, Cr2, Fe2, La2, Mo2, Na2, Rb2, Sc2, Zr2), although all are presented in the data listing (Appendix B). A summary of laboratory duplicate and control data is included in this report, and detailed data are available on request from the first author.

STATISTICAL ANALYSIS – FREQUENCY DISTRIBUTIONS

The frequency distributions of the geochemical data were examined using the Jenks optimization method, also known as the goodness of variance fit (Jenks, 1967) found within the ArcMap GIS application. The method identifies natural breaks in the dataset, and has replaced the selection of breaks using cumulative frequency plots (*cf.*, Batterson and Taylor, 2001). Comparison of the two method produced similar subdivisions of the data. Breaks in slope of the curves were used to subdivide the element values into 4-6 natural population groups. These groups are represented by symbols that increase in size with increasing element levels in Figure 5 to Figure 50. Statistics (maximum, minimum, median, mean, standard deviation) were generated from the Excel software application, and are presented in Table 5. A correlation matrix is shown in Table 6.

Table 3. Accuracy of till-geochemical data by INAA. Results of analyses of CANMET reference samples TILL-1 to -4. Observed values (Obs) are compared against recommended values (Rec). Recommended values are from Lynch (1996)

DISPERSAL FROM THE STRANGE LAKE DEPOSIT

The Strange Lake deposit, which is distinctly different, geologically, from the surrounding bedrock, forms a topographic high that straddles the Labrador–Québec border; down-ice of the deposit is a peneplain surface that has few topographic impediments to dispersal train development. Ice-flow directions are generally unidirectional. The area is, therefore, ideal for development of a classic ribbon-shaped dispersal train.

INTERPRETATION OF GEOCHEMICAL DATA

Dot plot maps of selected elements (Au, Be and U) are presented in Figures 5 to 7, respectively. Other element plots are presented in Appendix B. Individuals and companies are encouraged to undertake their own interpretation of the presented data, the following being a preliminary guide. Data on mineral occurrences are found within the Geological Survey's Mineral Occurrence Data System (MODS) (<http://gis.geosurv.gov.nl.ca/mods/mods.asp>).

Gold (Au)

The maximum value for gold in the Strange Lake area is 287 ppb, located in the northwestern part of the surveyed area (Figure 5). This sample is part of a cluster of elevated gold values in till overlying gabbro-norite bedrock (Unit P1:CG of Ryan *et al.*, 2003). The gold in till data is often difficult to interpret, and shows a spotty distribution. The small (<1 kg) sample size is likely a factor. Caution needs to be exercised when interpreting anomalies because of the ‘nugget effect’. It is recognised that heavy mineral sep-

Table 5. Units, detection limits, ranges, medians and standard deviations of geochemical data. Values below detection are coded as half of the detection limit value

arations from an initially larger sample size (>4 kg) would likely yield more reproducible gold geochemistry data (e.g., McClenaghan *et al.*, 1997).

Gold is poorly correlated with all other elements analysed (Table 6) and laboratory duplicates showed a high degree of correlation (0.972, Table 4).

Beryllium (Be)

The highest value for beryllium is 23 ppm, located in a cluster of relatively high values over the Strange Lake deposit (Figure 6). Other high values (up to 16 ppm) are found in the well-developed dispersal train that extends down-ice of the complex for at least 40 km. The pattern seen for beryllium is similar to that defined for other known deposit-related elements; yttrium (Figure 47), niobium (Figure 31), zirconium (Figure 50), REEs (except europium; Figure 20), and associated elements, including selenium (Figure 38), lithium (Figure 25), lead (Figure 34), rubidium (Figure 35), tantalum (Figure 41), thorium (Figure 43), uranium (Figure 7) and zinc (Figure 49). Other elements show the inverse pattern. Cobalt (Figure 15), for instance, shows relatively low values within the dispersal train from the Strange Lake deposit compared to areas north and south of the deposit. Magnesium (Figure 27), scandium (Figure 37), strontium (Figure 40) and titanium (Figure 44) all show similar trends to that of cobalt.

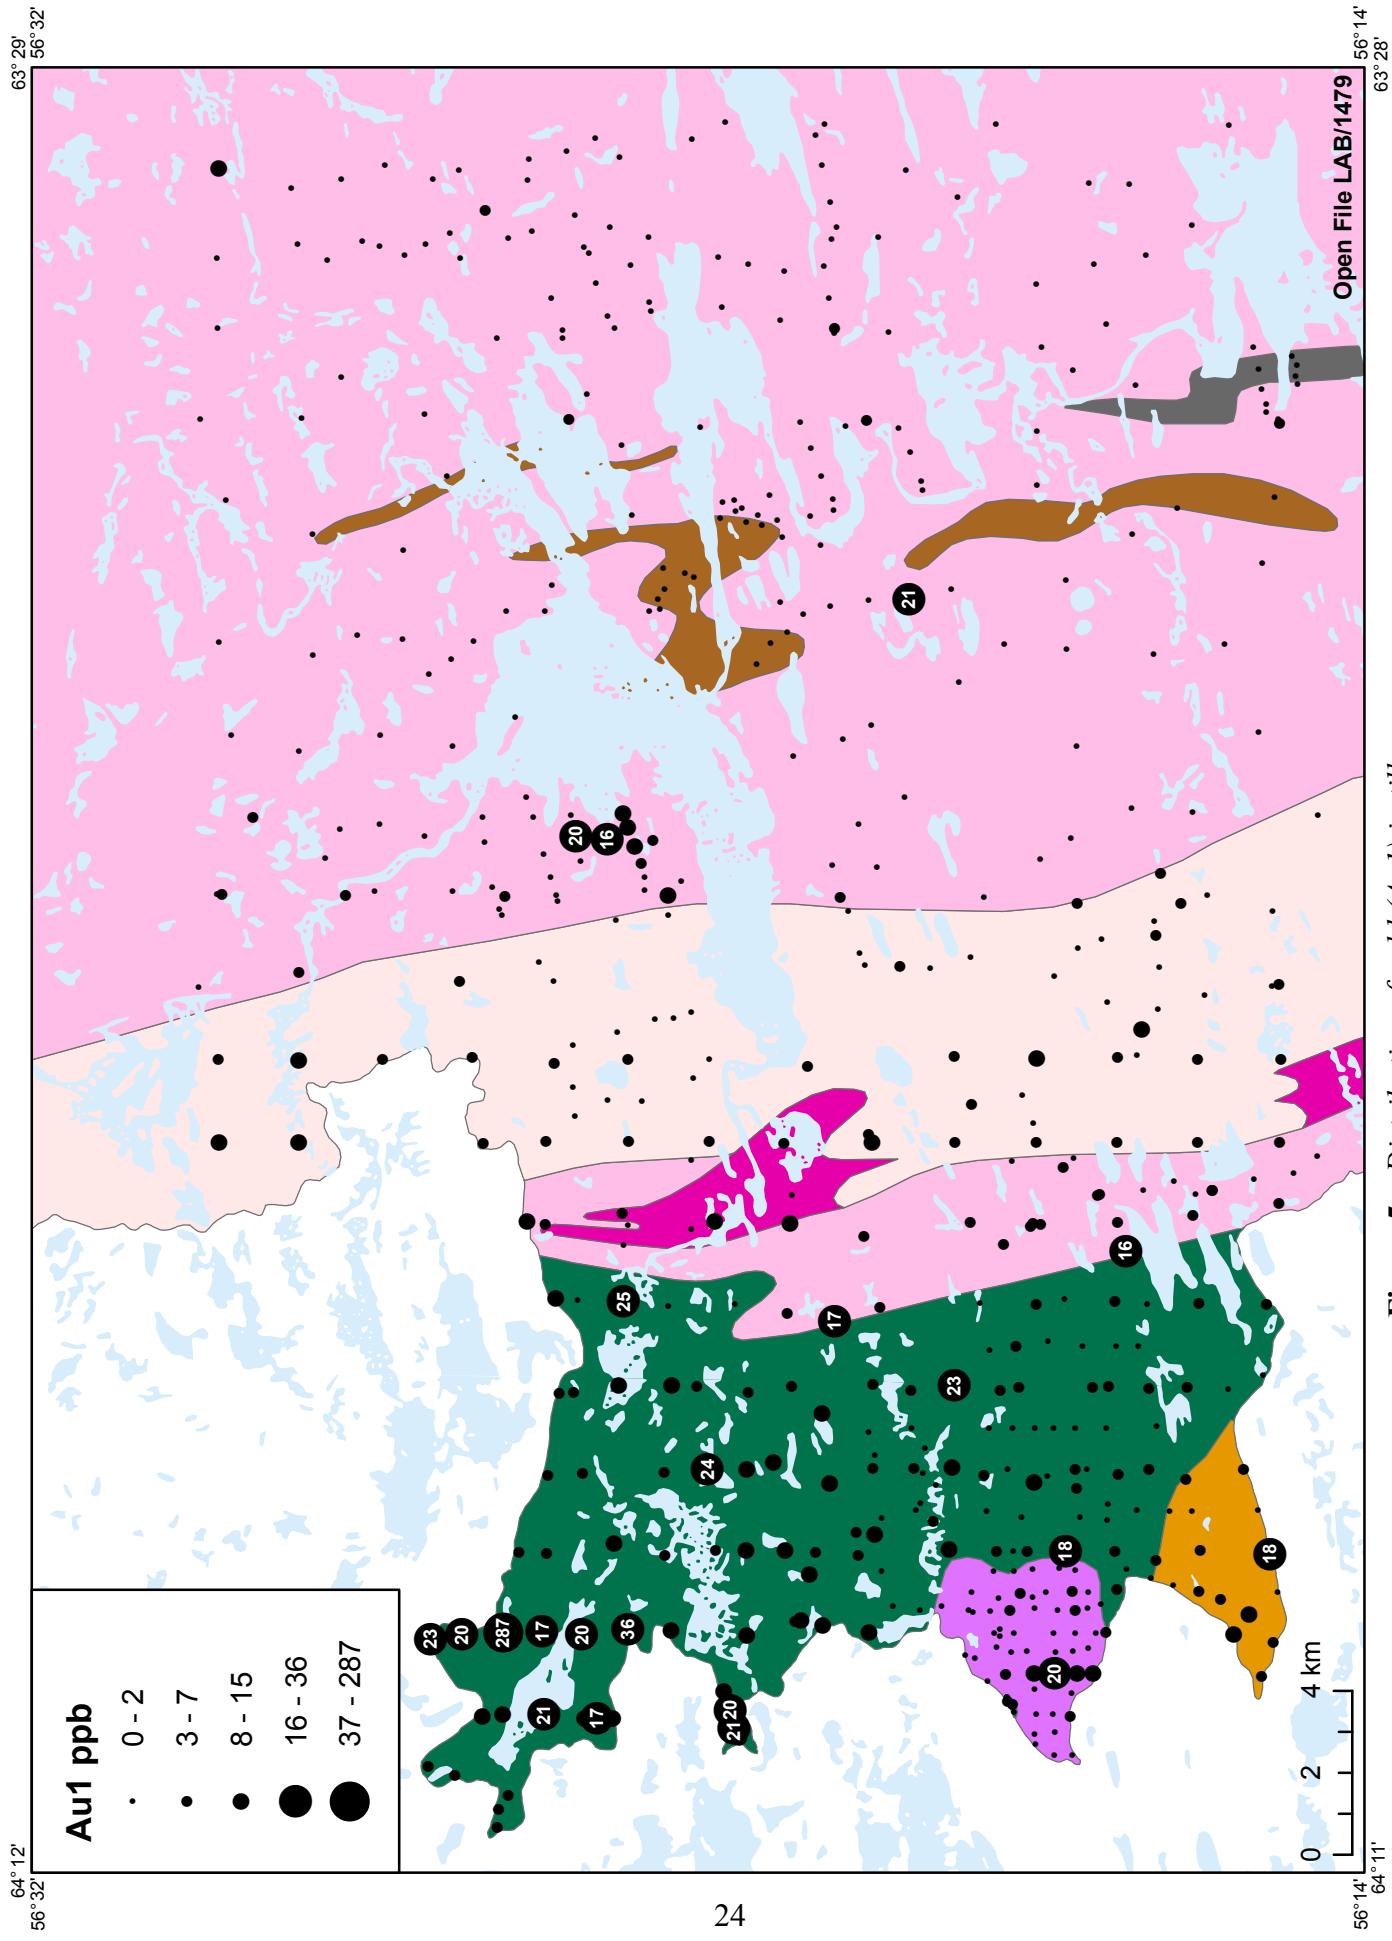

Figure 5. Distribution of gold (Au1) in till.

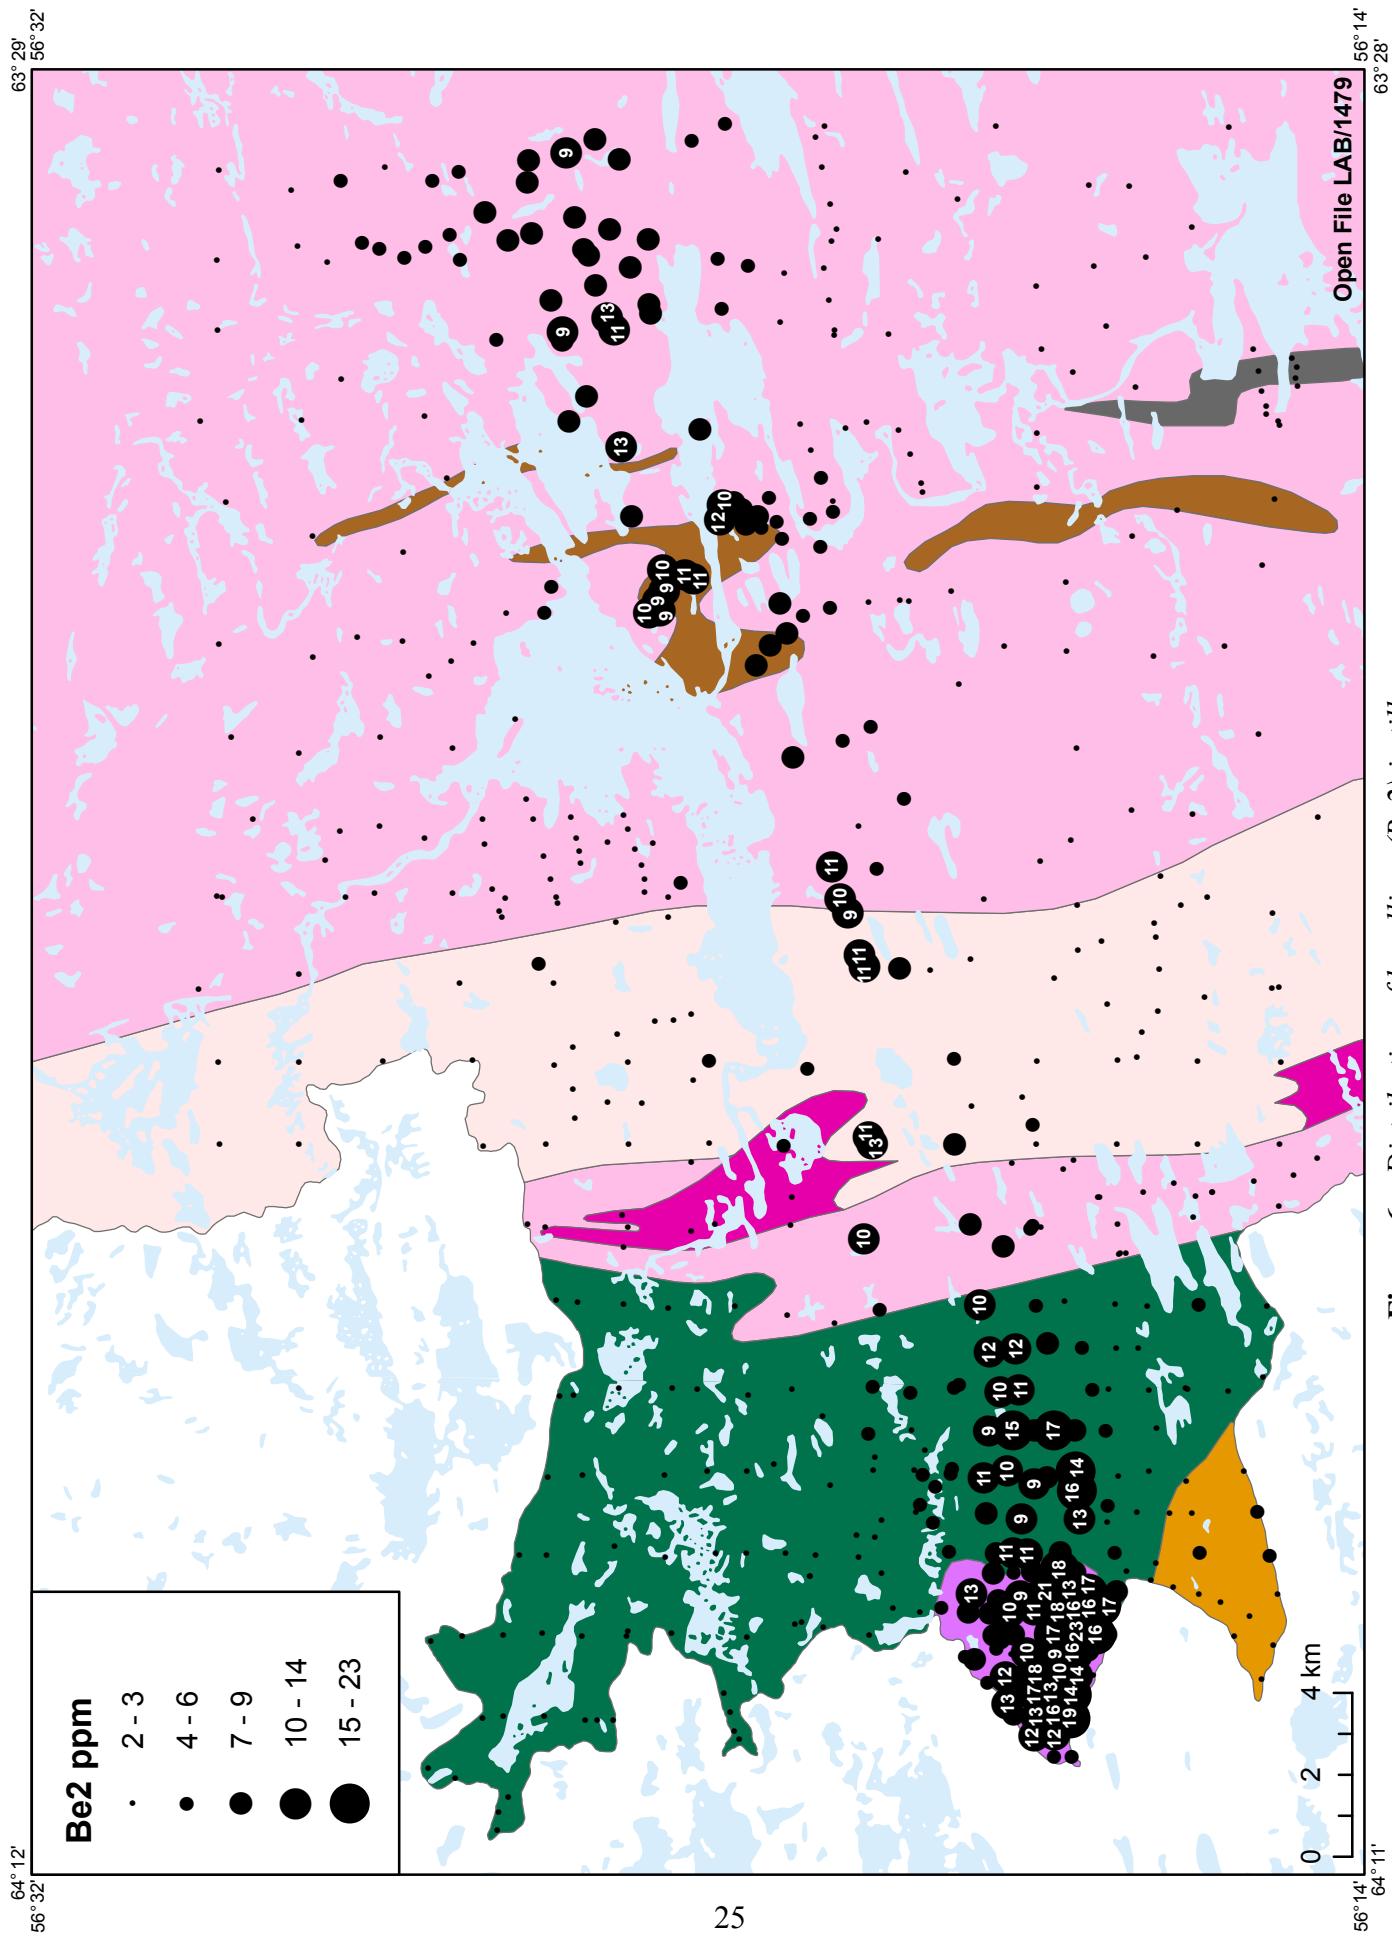

Figure 6. Distribution of beryllium (*Be2*) in till.

Beryllium shows high degree of correlation (Table 6) with all REE analysed (Ce, Dy, La, Lu, Tb, Sm, Yb), except europium (0.441), as well as niobium (0.959), tantalum (0.953), zirconium (0.943), lead (0.863), zinc (0.849), lithium (0.848), hafnium (0.815) and selenium (0.801). Laboratory duplicates showed a high degree of correlation (Table 4), and the data is thus considered accurate.

Uranium (U)

The highest value for uranium in till is 19.3 ppm, found overlying the Strange Lake deposit (Figure 7). Other relatively high values are found within the dispersal train from the deposit.

Uranium is correlated with other deposit-related elements, including beryllium (0.712), cerium (0.809), dysprosium (0.830), lanthanum (0.830), terbium (0.838), thorium (0.827), yttrium (0.831), and ytterbium (0.796). Miller (1986) reports up to 212 ppm uranium from bedrock within the exotic-rich phase of the deposit. Laboratory duplicates showed a high degree of correlation (Table 4), and the data is thus considered accurate.

DISCUSSION

The geochemical dispersal patterns from the Strange Lake deposit have been described in detail by McConnell and Batterson (1987) and Batterson (1989a). The dispersal patterns vary widely between the elements. A group of elements including Be, Pb, U, Th, Y and Zr highlight the area of mineralization, whereas others (*e.g.*, Co, Ni and Cu) reflect either the gneissic terrane to the north or dispersion from the adamellites to the south. To more fully understand the inter-elemental associations, a Pearson correlation coefficient matrix was generated (Table 6). The table shows that elements having strong correlations (greater than 0.8) fall neatly into two groups. The first group consists of Co, Ni and Cu, which likely reflects a mafic component of the gneissic terrane. The second group is of lithophile elements associated with the ore elements of the Strange Lake deposit (Be-La-Nb-Pb-U-Y-Zr). Analysis of this second group shows that the patterns of dispersal are broadly similar (*e.g.*, Figures 5 and 31).

The highest values are clustered over the peralkaline granite and the mineralized zone, in particular, and the dispersal train extends parallel to ice movement as interpreted from ice-flow direction indicators. The train is ribbon-shaped, although some fanning occurs beyond 30 km down-ice. The train is clearly delineated for at least 40 km down-ice of the deposit. The geochemical contrast between the peralkaline-related dispersal train and local background over the gneissic terrane to the north is sharp. The difference between the peralkaline granite dispersal pattern and that of the adamellite is clear, although less pronounced. This is a reflection of more elevated ore-related element values within the adamellite than in the gneissic terrane.

The geochemical dispersal pattern shows anomalies in all deposit-related elements, about 15 km and 25 km respectively, down-ice of the deposit (*e.g.*, Figure 6). Regional geology maps show that the areas underlying the anomalies are Archean gneisses and are thus not related to any suitable mineralization (Ryan *et al.*, 1988). These anomalies, therefore, correspond to either unknown mineralization or, more likely, are related to the mode of till deposition and are associated with the peralkaline granite. Of note is the fact that the anomalies correspond to topographic highs, and it was speculated by Batterson (1989b)

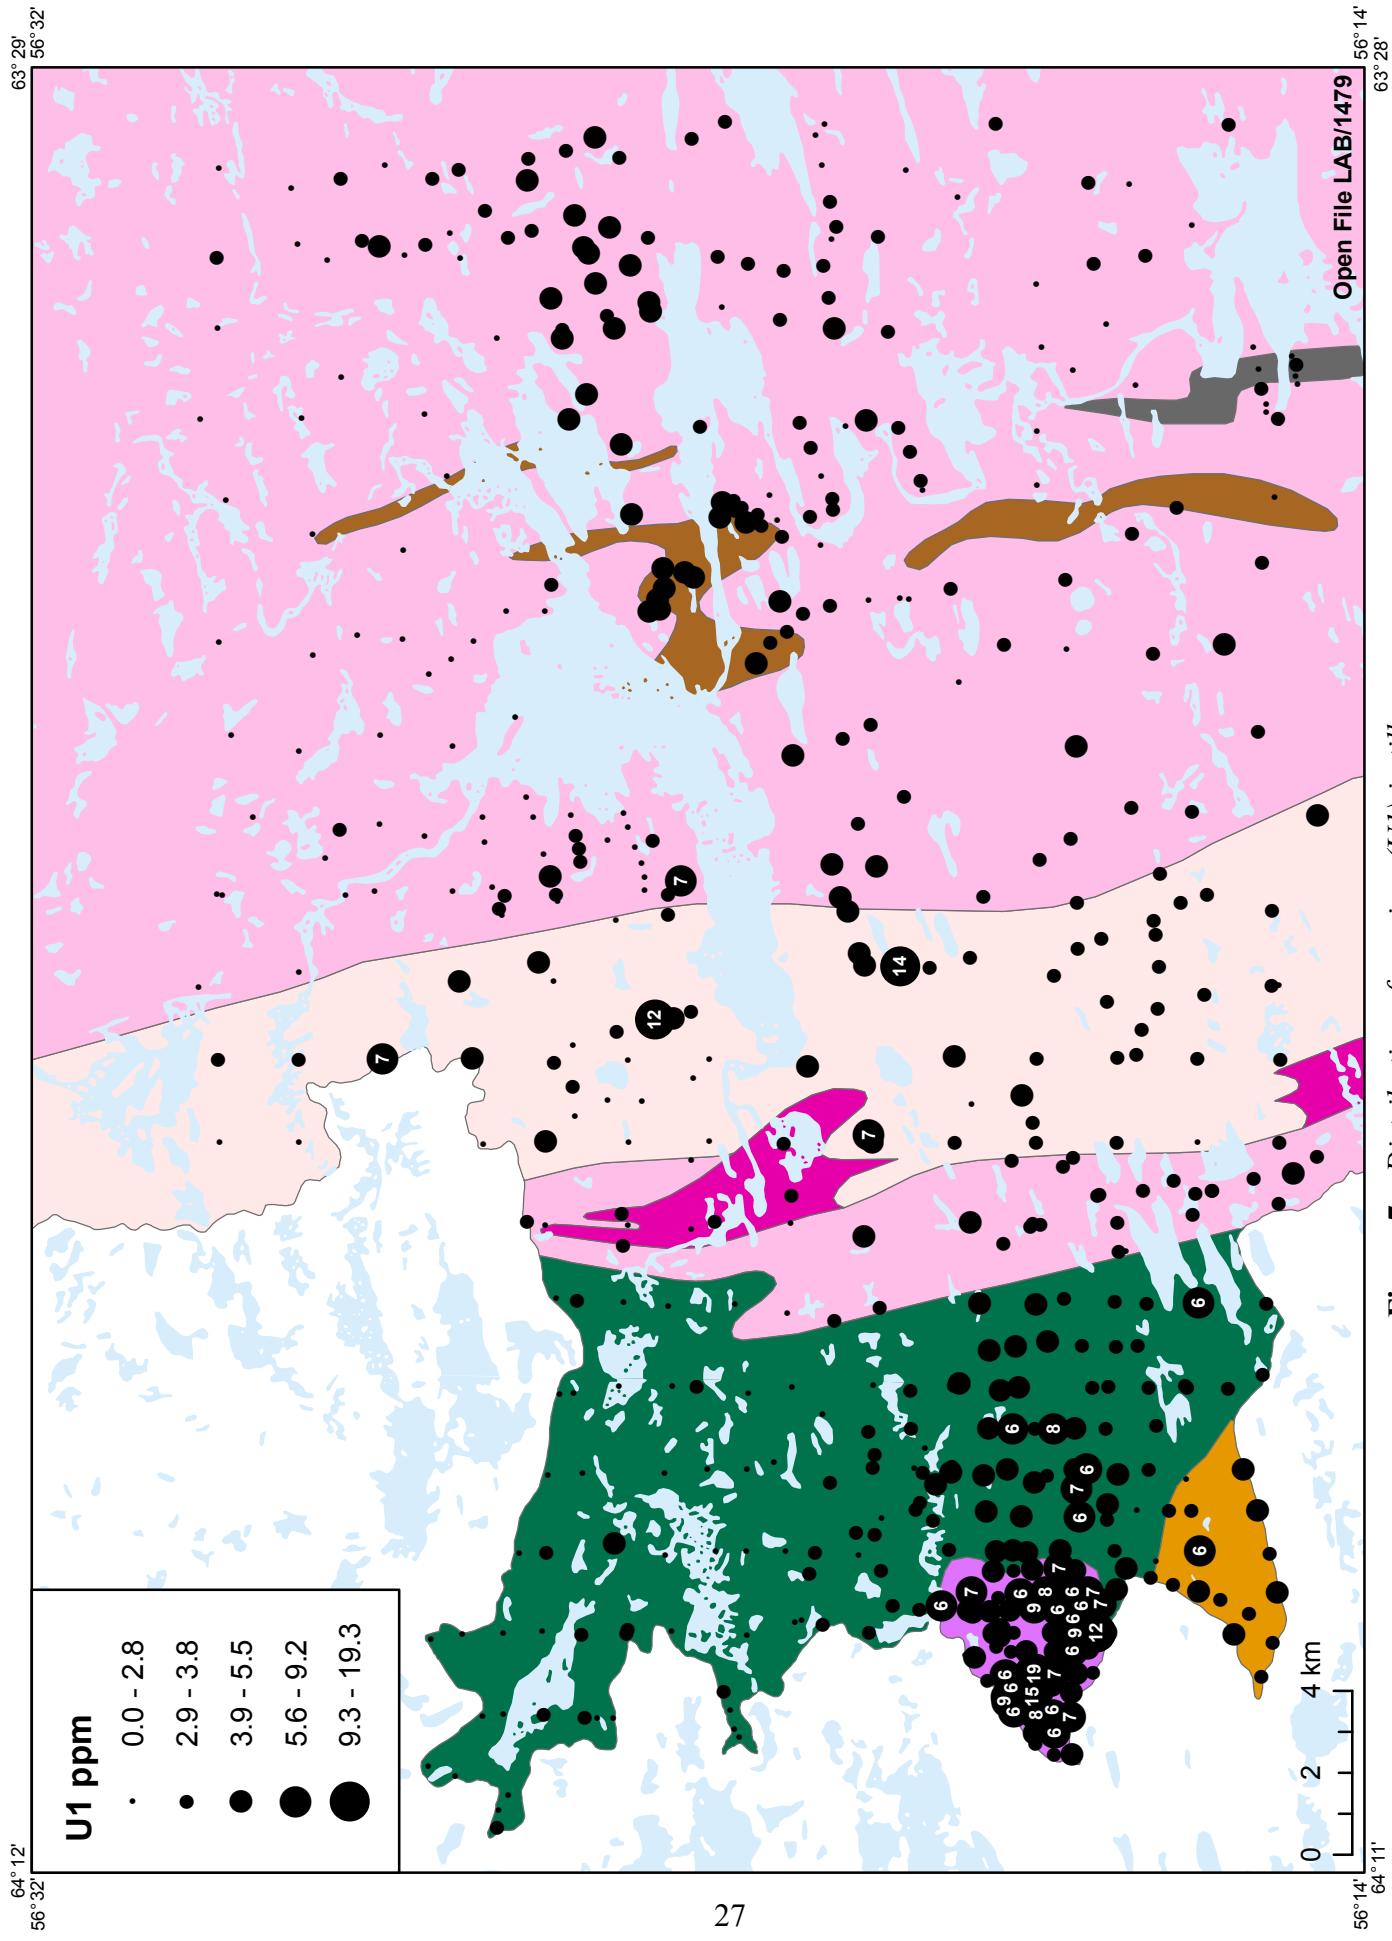

Figure 7. Distribution of uranium (U_1) in till.

that these obstructions intercepted englacial till planes that were enriched in sediment derived from the Strange Lake deposit.

GLACIAL TRANSPORT WITHIN THE STRANGE LAKE AREA

The geochemical properties of the till are the result of a complex response to glacial dispersal from the Strange Lake deposit. Batterson (1998) showed that the characteristics of the dispersal trains are similar in both till geochemistry and clast-dispersal studies. These characteristics provide an insight into the modes of glacial transportation and deposition within the area.

Comparison of the till-pebble lithology and trace-element concentrations, along a transect oriented parallel to glacial flow, showed corresponding highs between the two (Batterson, 1989a). All the anomalies occur down-ice of the deposit, within the dispersal train. It has been shown, taking into consideration both geochemical and clast data, that these anomalies commonly correspond to topographic highs, notably crag-and-tail hills. The well-defined anomalies within the Strange Lake dispersal train suggest long transport distances for much of the sediment. From the extent of the dispersal train, it is unlikely that glacial material was transported in the basal layers of the ice and deposited as lodgement tills because these are characteristically short-transported. Instead, it is likely that material was transported passively in the ice near the base, but not in contact with the substrate. The thin lodgement tills in the area, and the widespread occurrence of thick glacial diamicton, which has characteristics of a basal melt-out till, suggest that much material was transported englacially by the Laurentide Ice Sheet.

The amount of erosion from the Strange Lake deposit and the spatial distribution of erosion are unknown. Data from diamond drilling indicates that overburden thickness commonly in excess of 20 m is found on the western flanks of the deposit, although if this represents a single depositional event is not known. Nevertheless, from the amount of dispersed material, it is likely that extensive erosion of the deposit has occurred. The deposit has a surface vertical extent of 120 m and if the whole deposit was available for erosion then the englacial debris package within the ice sheet must have been extensive. Bedrock crags intercepted the englacial debris planes and induced deposition, resulting in the formation of crag-and-tail hills. Lowland areas, which have low deposit-related geochemical values compared to adjacent topographic highs, and are commonly below the elevation of the Strange Lake deposit, received material deposited by lodgement or melt-out during the waning phases.

DISPERSAL FROM THE STRANGE LAKE DEPOSIT: A SUMMARY

The Strange Lake deposit consists of rock types that are mineralogically, visually and chemically distinctive from the surrounding gneiss and adamellite terrane. The deposit has been well defined by diamond drilling and is consequently of known character and extent. Glacial dispersal has been characterized by detailed descriptions of geochemical and lithological trends across the Strange Lake area, and provides a model for glacial dispersal that may be applied to areas where the source of mineralisation is not known. A number of important issues generally related to exploration within drift-covered areas have arisen from this study. The major points of the report are summarized below.

- 1) The Strange Lake area was covered by late Wisconsinan ice that flowed eastward ($\sim 070^\circ$). Of the major sediment types found within the study area, till covers about 60 percent of the surface area. Basal

melt-out till dominates and this suggests a mainly englacial transportation mode for the sediments. Outwash deposits are restricted to several broad, shallow valleys in which well-developed esker ridges, commonly reaching 20 m in height, are evident. These outwash channels follow the trends of deglaciation in the area.

2) Batterson (1989a) showed that between-horizon geochemical data for most elements analysed, indicated a significant difference between the B- and BC- and between the B- and C-horizons for all the elements except Ga, Pb and V. No significant variation occurred between BC and C horizon data, except for Zr. This suggests that geochemical samples representative of the parent material can be taken from any distance below the recognizable B-horizon.

3) Mudboils are easy to sample and provided C-horizon till samples, but they do not occur uniformly across the Strange Lake area. Batterson (1989a) compared the geochemistry of mudboil samples with adjacent C-horizon samples and suggested that a less than 10 percent variation existed for deposit-related elements and that data may be combined in a regional sampling program.

4) Consistency in sampling of specific glacigenic sediment types is essential for determining accurate dispersal patterns. The well known contrast between eskers and till samples is noted (*e.g.*, Shilts, 1982). Also of importance, is the difference in values between samples taken near the crag or on the ramp of a crag-and-tail hill compared to the adjacent lowlands. The anomalous geochemical values that were identified at certain places along the dispersal train reflect topography rather than adjacent mineralization. In a regional till-sampling survey, and in an area dominated by glacial sediments, the combination of data from hilltops and intervening lowlands may lead to erroneous conclusions regarding the source of anomalies. Similarly, the position of sampling along a crag-and-tail hill is also important. The ramp/crag area consistently has the highest geochemical values, whereas samples immediately down-ice of the crag consistently have the lowest. Similar results were found in an examination of clast dispersal (Batterson, 1989a). The genesis of crag-and-tail features and the fact that most material eroded from the crag was deposited a short distance down-ice of it, thus, diluting any material deposited from an englacial position, are suggested as the reasons for this. It does identify, however, the need for careful sampling programs in areas dominated by these features.

5) The dispersal train defined by the geochemistry results of the samples collected is oriented parallel to glacial flow and has a ribbon-shaped pattern that is very close to the width of the mineralized complex for at least 40 km down-ice.

6) The geochemical dispersal train of the Strange Lake deposit is clearly defined through single-element maps. The mineralization is best identified by the elements Be, La, Nb, Pb and Y. A group consisting of Ce, Rb, Th, U and Zr also focused on the deposit, although not as clearly.

7) A sampling pattern of 1 sample per 2.5 km² adequately identifies the large dispersal train from the Strange Lake deposit, and is a suitable sample pattern for drift exploration surveys for deposits of this size.

Analysis of dispersal from such unique deposits as the Strange Lake deposit is rare. It provides the opportunity to identify many of the effective exploration techniques for use in drift-covered areas. The

results of such a study may be applied to projects in other drift-covered areas, where the bedrock source of the mineralized clasts is presently unknown.

ACKNOWLEDGMENTS

The Strange Lake till geochemistry project was completed in 1983 and 1984. Field assistance was provided by Spencer Vatcher, Denis Fox, Sandra Hookey and Sharon Scott, with expediting provided by Wayne Tuttle, and with helicopter support supplied by Sealand Helicopters.
